Abstract—A sphere decoder searches for the closest lattice point within a certain search radius. The search radius provides a tradeoff between performance and complexity. We derive tight upper bounds on the performance of sphere decoding of linear block codes. The performance of soft-decision sphere decoding on AWGN channels as well as that of hard-decision sphere decoding on binary symmetric channels is analyzed.

I. INTRODUCTION

Maximum likelihood (ML) decoding of linear block codes is known to be NP-hard [1]. Fincke and Pohst (FP) [2] described a ‘sphere decoder’ algorithm for closest point search in lattices which could find the closest lattice point to the received vector without actually searching all the lattice points. A fast variation of it was given by Schnorr and Euchner [3]. Other efficient closest point search algorithms exist (for a survey see [4]). The sphere decoder algorithm was proposed for decoding lattice codes [5]. Recently, a soft-decision (SD) sphere decoder was used for joint detection and decoding of linear block codes [6]. A hard decision (HD) sphere decoder was proposed for decoding linear block codes over the binary symmetric channel (BSC) [7]. The decoding radius of the sphere decoder provides a tradeoff between performance and complexity.

Tight upper bounds on the performance of SD-ML decoding of linear block codes over additive white Gaussian noise (AWGN) channels were derived in the literature (e.g., [8], [9], [10] and references therein). A tight bound on the performance of the HD-ML decoder on the BSC is the Poltyrev bound [8].

In this paper, we find tight upper bounds on the performance of HD and SD sphere decoding of linear block codes when transmitted over the BSC and AWGN channels respectively. This is done in sections II and III respectively. The performance of sphere decoding of Reed Solomon codes is analyzed in section IV. In section V, the analytic bounds are compared to simulations. In section VI, we conclude the paper.

II. UPPER BOUNDS ON THE PERFORMANCE OF SOFT DECISION SPHERE DECODING

Throughout this paper, C will denote an (n, k) binary linear code. Assuming that a codeword \( c \in C \) is transmitted over a binary input AWGN channel, the received word is \( y = x + z \), where \( x = M(c) \), \( M(c) \Delta = 1 - 2c \) is the BPSK modulation of \( c \) and \( z = [z_i]_{i=1}^{n} \) is the AWGN vector with variance \( \sigma^2 \).

A soft-decision sphere decoder with an Euclidean radius \( D \), SSD(D), solves the following optimization problem,

\[
\hat{c} = \arg \min_{\|v\| \leq D} \|y - M(v)\|^2
\]

(1)

subject to \( \|y - M(v)\|^2 \leq D^2 \),

where \( \|x\| \) is the Euclidean norm of \( x \). Such decoders include list-decoders that list all codewords whose modulated image is within an Euclidean distance \( D \) from the received vector \( y \) and choose the closest one.

Let \( \mathcal{E}_D \) denote the event of error or failure of SSD(D), then the error plus failure probability, \( P(\mathcal{E}_D) \) \(^1\) is

\[
P(\mathcal{E}_D) = P(\mathcal{E}_D|\mathcal{E}_{ML})P(\mathcal{E}_{ML}) + P(\mathcal{E}_D|S_{ML})P(S_{ML}),
\]

(2)

where \( \mathcal{E}_{ML} \) and \( S_{ML} \) denote the events of an ML error and an ML success respectively. Let \( \epsilon = \|y - M(\epsilon)\| \), then an ML error results if there exists another codeword \( \hat{c} \in C \) such that \( \|y - M(\hat{c})\| \leq \epsilon \). Since limiting the decoding radius to \( D \) will not do better than ML decoding, then \( P(\mathcal{E}_D|\mathcal{E}_{ML}) = 1 \). Since \( P(S_{ML}) \leq 1 \), it follows that an upper bound on the decoding performance is

\[
P(\mathcal{E}_D) \leq P(\mathcal{E}_{ML}) + P(\mathcal{E}_D|S_{ML}).
\]

(3)

Let \( \Omega_D \) be the Euclidean sphere of radius \( D \) centered around the transmitted codeword. The probability that the added white Gaussian noise will not lie in the sphere \( \Omega_D \) is

\[
P(z \notin \Omega_D) = P(\chi_n > D^2) = 1 - \Gamma_r(n/2, D^2/2\sigma^2)
\]

(4)

where \( \chi_n = \sum_{i=1}^{n} z_i^2 \) is a Chi-squared distributed random variable with \( n \) degrees of freedom. Let \( \Gamma(x) \) denote the Gamma function, then the cumulative distribution function (CDF) of \( \chi_n \) is given by the regularized Gamma function \( \Gamma_r \) [11],

\[
\Gamma_r(v/2, w/2) = \begin{cases} 
\int_0^w \frac{t^{v/2-1}e^{-t/2}}{2^{v/2}\Gamma(v/2)}\,dt, & w \geq 0; \\
0, & w < 0.
\end{cases}
\]

(5)

Define \( \hat{P}(\mathcal{E}_{ML}) \) to be an upper bound on the SD-ML decoder error probability, then we have the following lemma,

**Lemma 1:** \( P(\mathcal{E}_D) \leq \hat{P}(\mathcal{E}_{ML}) + P(z \notin \Omega_D) \).

\(^1\)Throughout out this paper, \( P(X) \) will denote the probability that the event \( X \) occurs.
Proof: Given an ML success, $E_D$ will only be due to failures of the SSD(D) decoder, i.e.,

$$P(E_D|S_{ML}) = P(\|y - M(c)\| > D) = P(z \notin \Omega_D),$$

where the last equality follows from the linearity of the code and without loss of generality one could assume that the all zero codeword was transmitted. By definition, $P(E_{ML}) \leq P(E_{ML})$. By substituting in (3) we are done. \(\blacksquare\)

Lemma 1 provides a way to bound the performance of sphere decoding of linear block codes on a variety of channels where additive white Gaussian noise is added and for a variety of modulation schemes. (In this paper, we will concentrate on the case that a binary linear block code is BPSK modulated and transmitted over an AWGN channel.) If $\hat{P}(E_{ML})$ is the union upper bound on the codeword error probability [12, Ch.8] for BPSK modulation on an AWGN channel, then

$$P(E_{ML}) \leq \sum_{w=0}^{D} G_w Q(\sqrt{2\gamma R w}) + P(z \notin \Omega_D),$$

where $G_w$ is the number of codewords with (binary) Hamming weight $w$, $\gamma$ is the signal to noise ratio (SNR) and $R$ is the rate of the code. Eq. 6 was used in [13] to bound the performance of a suboptimum decoder, used for soft decoding of Reed Solomon codes when their binary image is used for transmission. Lemma 1 implies that one could obtain a tighter upper bound on $P(E_D)$ by tightening the bound on the ML error probability, $\hat{P}(E_{ML})$.

Shannon’s sphere packing bound [14] is a lower bound on the error probability where he showed that the Voronoi region of a codeword can be bounded by a right circular $n$-dimensional cone with the codeword on its axis. The Poltyrev tangential sphere bound (TSB) on the performance of the SDML decoder is calculated by,

$$P(E_{ML}) \leq \min_{\theta} \{ P(E_{ML}, z \in V_\theta) + P(z \notin V_\theta) \},$$

where $V_\theta$ is an $n$-dimensional right circular cone with a half angle $\theta$ whose central line passes through the transmitted codeword and whose apex is at an Euclidean distance $\sqrt{n}$ from the transmitted codeword. Let the minimum of the optimization problem in (7) be achieved at $\theta = \phi$, then the following upper bound is tighter than (6),

$$P(E_D) \leq P(E_{ML}, z \in V_\phi) + P(z \notin V_\phi) + P(z \notin \Omega_D).$$

(8)

For the TSB, the optimum angle $\phi$ is related to the radius $\sqrt{\rho_\phi}$ (see Fig. 1 or Fig. 2) by $\sqrt{\rho_\phi/n} = \tan(\phi)$, such that $\rho_\phi$ is the root of

$$\sum_{l=1}^{n} G^l_{\phi}(r_\phi) \int_{\theta_{1(l)}}^{\theta_{2(l)}} \sin^{n-2}(\theta) d\theta = B$$

(9)

when solved for $r_\phi$ [8], $B \triangleq \frac{\sqrt{n}(\frac{2}{2})^{\frac{n}{2}}}{\Gamma(\frac{n}{2})}$ and $\theta_{1(l)} \triangleq \cos^{-1}\left(\sqrt{\frac{b/r_\phi}{1-b/n}}\right)$, $\theta_{2(l)} \triangleq \cos^{-1}\left(\sqrt{\frac{b/r_\phi}{1-b/n}}\right)$. Define $\alpha_b(r_\phi) \triangleq r_\phi(1 - b/n)$, $G^l_{\phi}(r_\phi) = G_b$ if $b < \alpha_b(r_\phi)$ and $G^l_{\phi}(r_\phi) = 0$ otherwise. Let $z_1$ be the component of the noise along the central axis of the cone with a probability distribution function (PDF) $N(z_1) = \frac{1}{\sqrt{2\pi n}}e^{-z_1^2/2n}$ and $z_2$ be the noise component orthogonal to $z_1$. Define $\beta_z(b) \triangleq \sqrt{\frac{z}{\frac{n}{2}}} + \sqrt{\frac{n}{2n}}$ and $r_z(\phi) \triangleq \sqrt{\frac{2}{n} - \frac{n}{2}}$, then the ML error probability given that the noise $z$ is in the cone $V_\phi$ is [8]

$$P(E_{ML}, z \in V_\phi) = \int_{\infty}^{-\infty} N(z_1) \left[ \sum_{l=1}^{n} G^l_{\phi}(r_\phi) \int_{\beta_z(b)}^{r_z(\phi)} N(z_2) \Gamma_r \left(n \frac{n - 2}{2}, \frac{r_z(\phi) - n_z}{2\sigma^2} \right) dz_2 \right] dz_1.$$  

(10)

A. A tight upper bound on the performance of SDD(D)

We observe that instead of directly substituting the TSB of (7) for $\hat{P}(E_{ML})$ in Lem. 1 as we did in (8), a tighter upper bound than (8) could be found by noticing that the events $\{ z \notin V_\phi \}$ and $\{ z \notin \Omega_D \}$ are not in general mutually exclusive. This is shown in the following lemma.

Lemma 2: $P(E_D)$ is upper bounded by $P(E_D) \leq P(E_{ML}, z \in V_\phi) + P(z \notin \Omega_D) + P(\{ z \notin V_\phi \} \cap \{ z \in \Omega_D \})$.

Proof: Using Bayes’ rule and defining the region $\Lambda(\theta, D) \triangleq \{ V_\phi \cap \Omega_D \}$ we get

$$P(E_D) \leq \min_{\theta} \{ P(E_D|z \in \Lambda(\theta, D))P(z \in \Lambda(\theta, D)) \} + P(E_D|z \notin \Lambda(\theta, D))P(z \notin \Lambda(\theta, D)).$$

(11)

From the definition of $\Lambda(\theta, D)$, it follows that $P(E_D, z \in \Lambda(\theta, D)) = P(E_{ML}, z \in \Lambda(\theta, D)) \leq P(E_{ML}, z \in V_\phi)$, where the last inequality follows from that $\Lambda(\theta, D) \subseteq V_\phi$. Using $P(E_D|z \notin \Lambda(\theta, D)) \leq 1$, it follows that

$$P(E_D) \leq \min_{\theta} \{ P(E_{ML}, z \in V_\phi) + P(z \notin \Lambda(\theta, D)) \} \leq P(E_{ML}, z \in V_\phi) + P(z \notin \{ V_\phi \cap \Omega_D \}).$$

(12)

The last inequality is due to the observation that $\phi$ does not necessarily minimize (12). By de Morgan’s law, $\{ V_\phi \cap \Omega_D \}^c = \{ \Omega_D \}^c \cup \{ V_\phi \}^c \cap \{ \Omega_D \}$, $\{ . \}^c$ is the complement of $\{ . \}$. \(\blacksquare\)

We consider two cases;
Case A: The sphere $\Omega_D$ lies totally inside the cone $V_\phi$. (See Fig. 1). This case is equivalent to the event $\mathbb{A} \triangleq \{ D \leq D_\phi \}$, where
\[
D_\phi = \sqrt{n} \sin(\phi),
\]
and will be called the critical decoding radius. It follows that
\[
P(\{ z \notin V_\phi \} \cap \{ z \in \Omega_D \}) = 0,
\]
which could be substituted in Lem. 2. Furthermore, since $\Delta(\theta, D) = \Omega_D$, it follows from (11) that a tighter upper bound is
\[
P(\mathcal{E}_D|\mathbb{A}) \leq P(\mathcal{E}_{ML}, z \in \Omega_D) + P(z \notin \Omega_D),
\]
where
\[
P(\mathcal{E}_{ML}, z \in \Omega_D) = \sum_{\{ \mathbb{B} \}} \int_{\mathbb{B}} N(z) \int_D \int_{\{ \mathbb{A} \}} d\mathbb{A}.
\]
Let $\delta$ be the half angle at which the cone $V_\delta$ is tangential to the sphere $\Omega_D$, $\delta = \sin^{-1}(D/\sqrt{n})$ (see Fig. 1), then another tight upper bound is
\[
P(\mathcal{E}_D|\mathbb{A}) \leq P(\mathcal{E}_{ML}, z \in V_\phi) + P(z \notin \Omega_D).
\]

Case B: The sphere $\Omega_D$ intersects the cone $V_\phi$. (See Fig. 2). This could be divided into two cases depending on the position of the apex of the cone. The apex of the cone does not lie in the sphere when $\sqrt{n} \sin(\phi) < D < \sqrt{n}$ (see Fig. 2a), and lies in the sphere when $D \geq \sqrt{n}$ (see Fig. 2b). In both cases the following analysis holds. Let the origin, $O$, of the $n$-dimensional space be at the transmitted codeword which is also the center of $\Omega_D$. Since the cone and the sphere are symmetrical around the central axis, we project on a two dimensional plane as in Fig. 2a. The radial component of the noise (along the axis of the cone) is $z$. The altitudes $G_\delta(\phi, D)$ and $y_\delta(\phi, D)$ at which the (double) cone intersects the sphere are found by substituting the line equation $P = P_1 + u(P_2 - P_1)$, where $P = (x, y)$, $P_1 = (0, \sqrt{n})$ and $P_2 = (2\sqrt{n}\tan(\phi), -\sqrt{n})$ into the quadratic equation of the sphere. Solving for $u$, it follows that
\[
u_{a,b} = \frac{4n \pm \sqrt{16n^2 - 16n \sec^2(\phi)(n - D^2)}}{8n \sec^2(\phi)},
\]
and $y_{a,b}(\phi, D) = y_1 + \nu_{a,b}(y_2 - y_1) = \sqrt{n}(1 - 2\nu_{a,b})$. It is easy to check that at $D = \sqrt{n}$, $u_{a,b} = 0$ and $y_\delta$ is at the apex of $V_\phi$. If $D > \sqrt{n}$ then the intersection at $y_\delta$ is in the lower nappe of the cone. It is also observed that $V_\phi$ and $\Omega_D$ do not intersect ($\Omega_D \subset V_\phi$) if $16n^2 < 16n \sec^2(\phi)(n - D^2)$ or equivalently $D < \sqrt{n} \sin(\phi)$ which is Case A.

Define $\mathbb{B}$ to be the event $\mathbb{B} \triangleq \{ D > \sqrt{n} \sin(\phi) \}$. The error probability is upper bounded by $P(\mathcal{E}_D|\mathbb{B}) \leq
\]
\[
P(\mathcal{E}_{ML}, z \in \Omega_D) + P(z \notin \Omega_D) = \int_{\{ y_\delta \in \Omega_D \}} N(z) \int_{\{ y_\delta \}} f_{n-1}(t) dt dz_1.
\]
To summarize the tight upper bound is given in the following theorem.

**Theorem 3:** The performance of the soft decision sphere decoder with an Euclidean decoding radius $D$ on an AWGN channel with noise variance $\sigma^2$ is upper bounded by:

A) If $D \leq \sqrt{n} \sin(\phi)$,
\[
P(\mathcal{E}_D) \leq P(\mathcal{E}_{ML}, z \in \Omega_D) + 1 - \Gamma_r(n/2, D^2/2\sigma^2);
\]

B) If $D > \sqrt{n} \sin(\phi)$,
\[
P(\mathcal{E}_D) \leq P(\mathcal{E}_{ML}, z \in \Omega_D) + 1 - \Gamma_r(n/2, D^2/2\sigma^2) + \int_{\{ y_\delta \in \Omega_D \}} N(z_1) dz_1,
\]
where $P(\mathcal{E}_{ML}, z \in \Omega_D)$ is given by (10), $r_\delta$ is the solution of (9), $r_\delta = n \tan^2(\phi)$ and $\delta = \sin^{-1}(D/\sqrt{n})$.

III. UPPER BOUND ON THE PERFORMANCE OF HARD-DECISION SPHERE DECODING

In this section, an upper bound on the performance of the hard-decision sphere decoder, when the code is transmitted over the BSC, is derived. Transmitting a binary codeword over an AWGN channel followed by hard decisions is equivalent to transmitting it on a BSC with a cross over probability
\[
p = Q(\sqrt{2R})
\]
where $\gamma$ is the bit signal to noise ratio. Let $y$ be the received word when the codeword $c$ is transmitted over an BSC channel. The HD sphere decoder with radius $m$, $\text{HSD}(m)$, finds the codeword $\hat{c}$, if it exists, such that
\[
\hat{c} = \arg\min_{c \in \mathcal{C}} d(y, v)
\]
subject to $d(y, v) \leq m$,
\[
d(y, v)
\]
where $d(y, v)$ is the Hamming distance between $y$ and $v$. Let $\zeta = d(y, c)$, then, from the linearity of the code, the probability that the received word is outside a Hamming sphere (ball) of radius $m - 1$ centered around the transmitted codeword is
\[
P(\zeta \geq m) = \sum_{l=m}^{n} \binom{n}{l} p^l (1 - p)^{n-l}.
\]
Poltyrev [8] derived a tight bound on the performance of the HD-ML decoder based on,

$$P(E_{ML}) \leq \min_m \left\{ P(E_{ML}, \zeta < m) + P(\zeta \geq m) \right\}. \quad (19)$$

The minimum of the above equation is at \(m_o\), where \(m_o\) is the smallest integer \(m\) such that [8]

$$2m G_6 \sum_{r=\lfloor \frac{m-1}{2} \rfloor}^m \left( \begin{array}{c} b \\ r \\ n-b \\ m-r \end{array} \right) \geq \left( \begin{array}{c} n \\ m \end{array} \right). \quad (20)$$

The joint HD-ML error probability given that \(\zeta < m\) is upper bounded by the union bound [8],

$$P(E_{ML}, \zeta < m) \leq \sum_{b=1}^{2(m-1)} G_b \sum_{r=\lfloor \frac{m-1}{2} \rfloor}^{m-1} \left( \begin{array}{c} b \\ r \\ n-b \\ s \end{array} \right) p^r (1-p)^{n-r-s} \sum_{i=0}^{m-r-1} \left( \begin{array}{c} m-b \\ i \end{array} \right) p^i (1-p)^{m-i}. \quad (21)$$

We now turn our attention to the HD sphere decoder with an arbitrary decoding radius. Let \(P(\Sigma_m)\), be the error plus failure probability of HSD(\(m-1\)), then \(P(\Sigma_m)\) could be written as

$$P(\Sigma_m) = P(\Sigma_m, \zeta < m) + P(\Sigma_m | \zeta \geq m) P(\zeta \geq m)$$

$$= P(E_{ML}, \zeta < m) + P(\zeta \geq m), \quad (22)$$

where we used the fact that \(P(\Sigma_m | \zeta \geq m) = 1\) and the observation that given that \(\zeta < m\), the conditional error probability of the HSD(\(m-1\)) and the HD-ML decoders are the same. The last term in the above equation is equal to the failure probability of the HSD(\(m-1\)) decoder. To develop a tight upper bound on \(P(\Sigma_m)\), we consider two cases:

**Case I: The decoding radius \(m \geq m_o\).** The upper bound of (22) could be written as

$$P(\Sigma_m | m \geq m_o) = P(E_{ML}, \zeta < m_o) + P(E_{ML}, m_o \leq \zeta < m) + P(\zeta \geq m).$$

It follows that

$$P(\Sigma_m | m \geq m_o) \leq P(E_{ML}, \zeta < m_o) + P(\zeta \geq m_o). \quad (23)$$

We observe that the upper bound reduces to that of the HD-ML case (19). By recalling that the minimum of (19) is achieved at \(m_o\), the bound of (22) is looser than (23) when \(m > m_o\).

The intuition behind this is that the performance of a sphere decoder with a decoding radius \(m_o-1\) or greater approaches that of the ML decoder. Moreover, it was shown in [8] that \(m_o\) is a lower bound on the covering radius of the code.

**Case II: The decoding radius \(m < m_o\).** Noticing that the sphere \(\{ \zeta < m \} \subseteq \{ \zeta < m_o \}\), \(P(\Sigma_m | m < m_o)\) is indeed given by (22).

Thus, we have proved the following theorem,

**Theorem 4:** The performance of a hard-decision sphere decoder with a decoding radius \(m-1\) when used over an BSC channel with a cross-over probability \(p\) is upper bounded by

$$P(\Sigma_m) \leq \left\{ \begin{array}{ll} P(E_{ML}, \zeta < m_o) + P(\zeta \geq m_o), & m \geq m_o; \\
P(E_{ML}, \zeta < m) + P(\zeta \geq m), & m < m_o, \end{array} \right.$$ 

where \(m_o\) is radius that minimizes (19) and is the solution of (20). \(P(\zeta \geq m)\) is given by (18) and \(P(E_{ML}, \zeta < m)\) is upper bounded by (21).

### IV. Sphere Decoding of RS Codes

We study the performance of Reed Solomon (RS) codes defined over \(F_{2^m}\) when their binary image is transmitted over an AWGN channel and the decoder is either a HD or SD sphere decoder. Tight upper bounds on the performance of the HD and SD maximum likelihood decoders were developed in [15] by averaging the Poltyrev bounds over all possible binary representations of the RS code. We use the same technique here to analyze the performance of the sphere decoders, where the average binary weight enumerator of the RS code (see [15]) would be used in conjunction with theorems 3 and 4 to derive averaged bounds on the performance of decoding RS codes with the SSD and HSD respectively.

### V. Numerical Results

In this section, the bounds developed for SD and HD sphere decoding are evaluated and compared with the performance of
of an HD sphere decoder with a (binary Hamming) radius closely upper bounds that of the HD-BM decoder. We observe that the average performance when its binary image is transmitted over an AWGN channel.

The HD-ML decoder has more than 8 dB coding gain over the corresponding sphere decoders, \[6\] and \[7\] respectively. The minimum distance of the (24, 12) Golay code is 8. For the SD sphere decoder, the critical decoding radius is \(D_\phi = 3.772\) (see (13)). At a codeword error rater (CER) of \(10^{-5}\), the SSD with an Euclidean radius of 4 has a near ML performance. The optimum Hamming radius for the HSD bound is \(m_o = 4\). As expected, a sphere decoder with radius \(m_o - 1\) or greater has a near ML performance. It is observed that the analytical bounds are very tight. Similar results were also observed for BCH codes.

In Fig. 5, we show bounds on the performance of HD decoding of the near half rate (31, 15) RS code over \(F_{32}\) when its binary image is transmitted over an AWGN channel. The HD-ML decoder has more than 2 dB coding gain over the Berlekamp Massey (BM) decoder \[16\], which can correct 8 symbol errors. We observe that the average performance of an HD sphere decoder with a (binary Hamming) radius 8 closely upper bounds that of the HD-BM decoder. The optimum decoding radius is 18 and the HSD has a competitive performance with a radius of 15. In Fig. 6, the performance of SD decoding of the (15, 11) RS code over \(F_{16}\) are shown. The critical decoding radius is \(D_\phi = 4.588\). As expected, the performance of a SSD with a larger decoding radius approaches that of the SD-ML decoder at a lower SNR.

**VI. CONCLUSIONS**

Bounds on the error plus failure probability of hard-decision and soft-decision sphere decoding of linear block codes were derived. By comparing with the simulations of the corresponding decoders these bounds are tight. The performance of sphere decoding of binary images of Reed Solomon codes was analyzed. Moreover, the bounds are extremely useful in predicting the performance of the sphere decoders at the tail of error probability when simulations are prohibitive.
